#### Abstract

Let $\mathbb{S}$ be a nonorientable surface. A collection of pairwise noncrossing simple closed curves in $\mathbb{S}$ is a blockage if every onesided simple closed curve in $\mathbb{S}$ crosses at least one of them. Robertson and Thomas [9] conjectured that the orientable genus of any graph $G$ embedded in $\mathbb{S}$ with sufficiently large face-width is "roughly" equal to one half of the minimum number of intersections of a blockage with the graph. The conjecture was disproved by Mohar [7] and replaced by a similar one. In this paper, it is proved that the conjectures in $[7,9]$ hold up to a constant error term: For any graph $G$ embedded in $\mathbb{S}$, the orientable genus of $G$ differs from the conjectured value at most by $O\left(g^{2}\right)$, where $g$ is the genus of $\mathbb{S}$.

## 1 Introduction

We follow standard graph theory terminology [2]. By a surface we mean a compact connected PL 2-manifold without boundary. The genus $\mathbf{g}(\mathrm{G})$

[^0]of a graph $G$ is the smallest integer $g$ such that $G$ has an embedding in the orientable surface $\mathbb{S}_{g}$ of genus $g$. The nonorientable surface of genus $g$ will be denoted by $\mathbb{N}_{g}$. So, $\mathbb{N}_{1}$ is the projective plane and $\mathbb{N}_{2}$ is the Klein bottle. The nonorientable genus of $G$ is the smallest $g$ such that $G$ admits an embedding in $\mathbb{N}_{g}$.

All embeddings of graphs in surfaces considered in this paper are 2-cell embeddings in which every face is homeomorphic to an open disk in the plane. If $\Pi$ is an embedding of a connected graph $G$ in some surface, the Euler genus of $\Pi$ is defined as the number $\operatorname{eg}(G, \Pi)=2-|V(G)|+|E(G)|-f$, where $f$ is the number of $\Pi$-facial walks. We refer to $[8]$ for additional information on embeddings of graphs in surfaces.

A closed curve on a surface $\mathbb{S}$ is a continuous PL mapping $\gamma: S^{1} \rightarrow \mathbb{S}$, and we sometimes identify $\gamma$ with its image $\gamma\left(S^{1}\right)$ in $\mathbb{S}$. If a graph $G$ is embedded in $\mathbb{S}$, then $\operatorname{cr}(\gamma, G)$ denotes the number of points $z \in S^{1}$ such that $\gamma(z)$ is a point of $G$ in $\mathbb{S}$. The curve $\gamma$ is onesided if every neighborhood of $\gamma$ on $\mathbb{S}$ contains a Möbius strip, and twosided otherwise.

## 2 The orientable genus of graphs with a given nonorientable embedding

Let $\Pi$ be a ( 2 -cell) embedding of a graph $G$ into a nonplanar surface $\mathbb{S}$, i.e. a surface distinct from the 2 -sphere. Then we define the face-width $\mathrm{fw}(G, \Pi)$ (also called the representativity) of the embedding $\Pi$ as the minimum number of facial walks of $G$ whose union contains a noncontractible curve. Alternatively, $\mathbf{f w}(G, \Pi)$ is the minimum $\operatorname{cr}(\gamma, G)$ taken over all noncontractible closed curves $\gamma$ on $\mathbb{S}$.

It is easy to see that the nonorientable genus of every graph $G$ is bounded by a linear function of the genus $\mathbf{g}(G)$. On the other hand, Auslander, Brown, and Youngs [1] proved that there are graphs embeddable in the projective plane whose orientable genus is arbitrarily large. This phenomenon is now appropriately understood after Fiedler, Huneke, Richter, and Robertson [3] proved that the genus $\mathbf{g}(G)$ of a graph $G$ that is $\Pi$-embedded in the projective plane equals

$$
\begin{equation*}
\mathbf{g}(G)=\left\lfloor\frac{1}{2} \mathrm{fw}(\Pi)\right\rfloor \tag{1}
\end{equation*}
$$

if $\mathrm{fw}(\Pi) \neq 2$. If $\mathrm{fw}(\Pi)=2$, then $\mathbf{g}(G)$ is either 0 or 1 .
This result has been generalized to the Klein bottle by Robertson and Thomas [9] as follows. Let $\Pi$ be an embedding of $G$ in $\mathbb{N}_{2}$. Denote by
$\operatorname{ord}_{2}(G, \Pi)$ the minimum of $\lceil\operatorname{cr}(\gamma, G) / 2\rceil$ taken over all noncontractible and nonseparating twosided simple closed curves $\gamma$. Similarly, let $\operatorname{ord}_{1}(G, \Pi)$ denote the minimum of $\left\lfloor\operatorname{cr}\left(\gamma_{1}, G\right) / 2\right\rfloor+\left\lfloor\operatorname{cr}\left(\gamma_{2}, G\right) / 2\right\rfloor$ taken over all pairs $\gamma_{1}, \gamma_{2}$ of nonhomotopic onesided simple closed curves. The latter minimum restricted to all noncrossing pairs $\gamma_{1}, \gamma_{2}$ of onesided simple closed curves is denoted by $\operatorname{ord}_{1}^{\prime}(G, \Pi)$. Let

$$
\begin{equation*}
g=\min \left\{\operatorname{ord}_{1}(G, \Pi), \operatorname{ord}_{2}(G, \Pi)\right\} \tag{2}
\end{equation*}
$$

and

$$
\begin{equation*}
g^{\prime}=\min \left\{\operatorname{ord}_{1}^{\prime}(G, \Pi), \operatorname{ord}_{2}(G, \Pi)\right\} \tag{3}
\end{equation*}
$$

Robertson and Thomas [9] proved that if $g \geq 4$, then $\mathbf{g}(G)=g=g^{\prime}$. Equations (1) and (2) imply that the genus of graphs that can be embedded in the projective plane or the Klein bottle can be computed in polynomial time.

By [11], genus testing is NP-complete for general graphs. Therefore, it is interesting that the classes of projective planar graphs and graphs embeddable in the Klein bottle admit a polynomial time genus testing algorithm. Very likely the genus problem for graphs with bounded nonorientable genus is solvable in polynomial time as suggested in [9].

Robertson and Thomas [9] conjectured that (1) and (2) can be generalized as follows. Suppose that $\Gamma=\left\{\gamma_{1}, \ldots, \gamma_{p}\right\}$ is a set of closed curves in the surface $\mathbb{N}_{k}$. Then $\Gamma$ is crossing-free if the following holds:
(a) No $\gamma_{i}$ crosses itself.
(b) For $1 \leq i<j \leq p$, the curves $\gamma_{i}$ and $\gamma_{j}$ do not cross each other.

If there exist simple closed curves $\gamma_{1}^{\prime}, \ldots, \gamma_{p}^{\prime}$ with pairwise disjoint images in $\mathbb{N}_{k}$ such that $\gamma_{i}^{\prime}$ is homotopic to $\gamma_{i}(i=1, \ldots, p)$ and such that every onesided closed curve in $\mathbb{N}_{k}$ crosses at least one of the curves $\gamma_{1}^{\prime}, \ldots, \gamma_{p}^{\prime}$, then we say that the family $\Gamma$ is a blockage and that $\Gamma$ blocks onesided curves in the surface.

Suppose that a graph $G$ is embedded in $\mathbb{N}_{k}$. Robertson and Thomas [9] define the order of a blockage $\Gamma=\left\{\gamma_{1}, \ldots, \gamma_{p}\right\}$ as

$$
\begin{equation*}
\operatorname{ord}(\Gamma, G)=\frac{1}{2}(k-2 p+s)+\sum_{i=1}^{p} \operatorname{ord}\left(\gamma_{i}, G\right) \tag{4}
\end{equation*}
$$

where $s$ is the number of onesided closed curves in $\Gamma$ and

$$
\operatorname{ord}\left(\gamma_{i}, G\right)= \begin{cases}\left\lfloor\operatorname{cr}\left(\gamma_{i}, G\right) / 2\right\rfloor, & \text { if } \gamma_{i} \text { is onesided } \\ \left\lceil\operatorname{cr}\left(\gamma_{i}, G\right) / 2\right\rceil, & \text { if } \gamma_{i} \text { is twosided. }\end{cases}
$$

Let us observe that the term $\frac{1}{2}(k-2 p+s)$ in (4) is an integer and that it is equal to the genus of the (bordered) orientable surface obtained by cutting $\mathbb{N}_{k}$ along the curves in $\Gamma$. It is easy to prove [9]:

Lemma 2.1. Let $G$ be a graph embedded in $\mathbb{N}_{k}$, and let $\Gamma$ be a blockage in $\mathbb{N}_{k}$. Then $\mathbf{g}(G) \leq \operatorname{ord}(\Gamma, G)$.

Based on (1)-(3) and Lemma 2.1, Robertson and Thomas proposed the following

Conjecture 2.2 (Robertson and Thomas [9]). Suppose that $G$ is embedded in $\mathbb{N}_{k}$ with sufficiently large face-width. Let $g$ (respectively $g^{\prime}$ ) be the minimum order of a blockage (crossing-free blockage) in $\mathbb{N}_{k}$ Then $\mathbf{g}(G)=$ $g=g^{\prime}$.

Mohar [7] disproved this conjecture and posed a related conjecture what the correct expression for $\mathbf{g}(G)$ might be (Conjecture 2.3 below). The value for the orientable genus of $G$ conjectured in [7] can differ only by a constant (depending on $k$ ) from the conjectured value of Robertson and Thomas.

Suppose that $G$ is embedded in $\mathbb{N}_{k}$. Consider a crossing-free blockage $\Gamma=\left\{\gamma_{1}, \ldots, \gamma_{p}\right\}$ and cut the surface $\mathbb{N}_{k}$ along $\gamma_{1}, \ldots, \gamma_{p}$. This results in a graph $\bar{G}$ embedded in an orientable surface. If a vertex $a \in V(G)$ lies on at least one of the curves $\gamma_{i}(1 \leq i \leq p)$, then $a$ gives rise to two or more vertices in $\bar{G}$ (called copies of $a$ ). Add a new vertex $v_{a}$ and join it to all copies of $a$ in $\bar{G}$. Call the resulting graph $G^{\prime}$ and note that contraction of the new edges results in the original graph $G$. Now, the orientable embedding of $\bar{G}$ defines local rotations of all vertices of $G^{\prime}$ except for the new vertices $v_{a}$. The minimum genus of an orientable embedding of $G^{\prime}$ extending this partial embedding is called the genus order of the blockage $\Gamma$. It is easy to see that in the case when no vertex of $G$ is split into more than two vertices of $\bar{G}$, the genus order coincides with (4), and that in general it is majorized by (4).

Conjecture 2.3 (Mohar [7]). If $G$ is embedded in a nonorientable surface with sufficiently large face-width, then the orientable genus of $G$ is equal to the minimum genus order of a crossing-free blockage.

In this paper it is proved that Conjectures 2.2 and 2.3 hold up to a constant error term, even without the assumption on large face-width. It is shown that for any graph $G$ embedded in $\mathbb{N}_{g}$, the orientable genus of $G$ differs from the minimum (genus) order of a crossing-free blockage for less than $(64 g)^{2}$. See Theorem 4.7.

## 3 Blocking onesided curves

Suppose that $G$ is a graph that is $\Pi$-embedded in some surface $\mathbb{S}$. We denote by $\Gamma=\Gamma(G, \Pi)$ the corresponding vertex-face graph. Its vertices are the union of vertices of $G$ and the vertices of the geometric dual $G^{*}$ of $G$, i.e., the $\Pi$-facial walks. The edges of $\Gamma$ correspond to the incidence of vertices and faces, with multiple edges if a vertex appears more than once on a $\Pi$-facial walk. The graph $\Gamma$ has a natural quadrilateral embedding in $\mathbb{S}$. The geometric dual of $\Gamma$, the graph which we shall denote by $M=M(G, \Pi)$, is known as the medial graph of $G$.

A set $B \subseteq E(M)$ is an edge-blockage in $M$ if every onesided cycle of $M$ contains an edge of $B$. If $B \subseteq E(M)$, let $B^{*} \subseteq E(\Gamma)$ be the set of dual edges, and let $\Gamma\left(B^{*}\right)$ be the subgraph of $\Gamma$ generated by $B^{*}$.

Lemma 3.1. Suppose that $G$ is $\Pi$-embedded in $\mathbb{N}_{g}$ and that $B \subseteq E(M)$ is an edge-blockage in $M$ that is minimal (with respect to inclusion). Then
(a) $\Gamma\left(B^{*}\right)$ is a bipartite Eulerian graph (possibly disconnected).
(b) The edge set $B^{*}$ of $\Gamma\left(B^{*}\right)$ can be partitioned into a set of edge-disjoint crossing-free closed walks. Any such partition into crossing-free closed walks is a crossing-free blockage in the surface.
(c) $\mathbb{N}_{g} \backslash \Gamma\left(B^{*}\right)$ is connected.
(d) Let $n_{i}$ be the number of vertices of degree $2 i+2$ in $\Gamma\left(B^{*}\right)$. Then

$$
\begin{equation*}
\sum_{i=0}^{\infty} i n_{i} \leq g-1 \tag{5}
\end{equation*}
$$

Proof. To prove claim (a), suppose that $\Gamma\left(B^{*}\right)$ contains a vertex $x$ of odd degree $d$. Let $e_{1}, \ldots, e_{d}$ be the edges in $B$ dual to the edges of $\Gamma\left(B^{*}\right)$ that are incident with $x$. By the minimality of $B$, there exist $\Pi$-onesided cycles $C_{i} \subseteq E(M) \backslash\left(B \backslash e_{i}\right), i=1, \ldots, d$. Let $C_{0}$ be the facial walk in $M$ that corresponds to the vertex $x$ of $\Gamma$. It is easy to see that the symmetric difference of the edges of these cycles, $C=C_{0}+C_{1}+\cdots+C_{d}$, contains a onesided cycle in $M$. This yields a contradiction since $C$ is disjoint from $B$.
(b) Any partition of $B^{*}$ into closed walks is obtained as follows. For each vertex $x \in V\left(\Gamma\left(B^{*}\right)\right)$, partition the edges incident with $x$ into pairs and then join the paired edges to form a collection $\mathcal{C}$ of closed walks in $\Gamma$ (which may be viewed as closed curves in $\mathbb{N}_{g}$ ). By choosing the pairs so that they are not crossing with any other chosen pair of edges incident with the
same vertex, none of the curves in $\mathcal{C}$ crosses itself and no two of them cross each other.

Suppose that there is a onesided simple closed curve $\gamma$ in $\mathbb{N}_{g}$ that crosses no member of $\mathcal{C}$. By elementary topology, it may be assumed that $\gamma$ does not intersect any edge of $\Gamma$ in its internal point, i.e., $\gamma$ passes through faces and vertices of $\Gamma$. Then $\gamma$ is determined (up to homotopy) by a cyclic sequence $v_{1} f_{1} v_{2} f_{2} \ldots v_{k} f_{k} v_{1}$ of vertices $v_{i} \in V(\Gamma)$ and faces $f_{i}$ of $\Gamma$ that are traversed by $\gamma$. Note that $f_{1}, \ldots, f_{k} \in V(M)$. For $i=1, \ldots, k$, let $S_{i}$ be a walk in $M$ that starts with the vertex $f_{i-1}$ of $M$, traverses a segment of the facial walk in $M$ which corresponds to $v_{i}$, and ends at $f_{i}$. Clearly, the closed walk $W$ in $M$ which is composed of $S_{1}, \ldots, S_{k}$ is homotopic to $\gamma\left(\right.$ in $\left.\mathbb{N}_{g}\right)$, so it is onesided. Since $\gamma$ crosses no curve from $\mathcal{C}$, each $S_{i}$ contains an even number of edges of $B$. Let $e_{1}, \ldots, e_{2 d}$ be the edges of $B$ that are traversed by $W$ an odd number of times and let $C_{1}, \ldots, C_{2 d}$ be as in the proof of part (a). Then $W+C_{1}+\cdots+C_{2 d}$ contains a onesided cycle that is disjoint from $B$, a contradiction.
(c) Suppose that $\mathbb{N}_{g} \backslash B^{*}$ is disconnected. Then there is an edge $e^{*} \in B^{*}$ such that on each side of $e^{*}$ there is a different component of $\mathbb{N}_{g} \backslash B^{*}$. Let $e \in$ $B$ be the edge which is dual to $e$. Let $C$ be a $\Pi$-onesided cycle in $M \backslash(B \backslash e)$. Since $C$ contains $e$, it intersects two components of $\mathbb{N}_{g} \backslash B^{*}$. Therefore, $C$ crosses $B^{*}$ at least twice, a contradiction.
(d) $\Gamma\left(B^{*}\right)$ is a graph in $\mathbb{N}_{g}$ having $n=\sum_{i} n_{i}$ vertices and $m=\sum_{i}(i+1) n_{i}$ edges. It may be disconnected, and its embedding in $\mathbb{N}_{g}$ may not be 2-cell. But Euler's inequality still holds: $n-m+f \geq \chi\left(\mathbb{N}_{g}\right)=2-g$. By (c), the number $f$ of connected components of $\mathbb{N}_{g} \backslash B^{*}$ is 1 , hence $\sum_{i} i n_{i}=m-n \leq$ $g-2+f=g-1$.

A vertex set $U \subseteq V(G)$ of a $\Pi$-embedded graph $G$ is a vertex-blockage if every $\Pi$-onesided cycle of $G$ contains a vertex in $U$. Similarly, a set $U^{*} \subseteq V\left(G^{*}\right)$ of $\Pi$-faces is a face-blockage if every onesided cycle in the dual graph $G^{*}$ contains a vertex in $U^{*}$. It is easy to see that $U^{*}$ is a face-blockage if and only if every onesided closed curve which does not contain vertices of $G$ intersects a face in $U^{*}$.

Lemma 3.2. Suppose that $G$ is $\Pi$-embedded in $\mathbb{N}_{g}$ and that $B \subseteq E(M)$ is an edge-blockage in $M$ that is minimal (with respect to inclusion). Let

$$
\begin{equation*}
U=V\left(\Gamma\left(B^{*}\right)\right) \cap V(G) \quad \text { and } \quad U^{*}=V\left(\Gamma\left(B^{*}\right)\right) \cap V\left(G^{*}\right) \tag{6}
\end{equation*}
$$

Then $U$ is a vertex-blockage, $U^{*}$ is a face-blockage in $G$, and the following
inequalities hold:

$$
\begin{align*}
2|U| & \leq|B| \leq 2|U|+2 g-2  \tag{7}\\
2\left|U^{*}\right| & \leq|B| \leq 2\left|U^{*}\right|+2 g-2  \tag{8}\\
|U|+\left|U^{*}\right| & \leq|B| \leq|U|+\left|U^{*}\right|+g-1 \tag{9}
\end{align*}
$$

Proof. Let $C$ be a $\Pi$-onesided cycle of $G$. By Lemma 3.1(b), $C$ intersects $\Gamma\left(B^{*}\right)$. Hence it intersects $U$. This proves that $U$ is a vertex-blockage. By duality, $U^{*}$ is a face-blockage.

To prove the first inequality of (7), observe that the minimum degree in $\Gamma\left(B^{*}\right)$ is $\geq 2$ (by Lemma 3.1(a)) and that $|B|$ equals the sum of degrees of vertices in $U$. To verify the second inequality, we shall apply Lemma 3.1(d) and denote by $n_{i}^{\prime}$ the number of vertices in $U$ whose degree in $\Gamma\left(B^{*}\right)$ is $2 i+2$. Then

$$
\begin{aligned}
|B| & =\sum_{u \in U} \operatorname{deg}(u)=2|U|+2 \sum_{i} i n_{i}^{\prime} \\
& \leq 2|U|+2 \sum_{i} i n_{i} \leq 2|U|+2(g-1)
\end{aligned}
$$

Similar proofs yield (8) and (9).
Let $\beta=\beta(G, \Pi)$ denote the vertex-blockage number, i.e. the minimum number of vertices in a vertex-blockage. Similarly, let $\beta^{*}=\beta^{*}(G, \Pi)$ be the face-blockage number (the minimum number of faces in a face-blockage), and $\beta^{\prime}=\beta^{\prime}(G, \Pi)$ the edge-blockage number (the minimum number of edges in an edge-blockage in $M$ ).

Corollary 3.3. Suppose that $G$ is $\Pi$-embedded in the nonorientable surface $\mathbb{N}_{g}$. Then the following inequalities hold:

$$
\begin{align*}
2 \beta & \leq \beta^{\prime} \leq 2 \beta+2 g-2  \tag{10}\\
2 \beta^{*} & \leq \beta^{\prime} \leq 2 \beta^{*}+2 g-2  \tag{11}\\
\beta+\beta^{*} & \leq \beta^{\prime} \leq \beta+\beta^{*}+g-1 \tag{12}
\end{align*}
$$

Proof. Let $B$ be a minimum edge-blockage, i.e. $|B|=\beta^{\prime}$. Then $U=\Gamma\left(B^{*}\right) \cap$ $V(G)$ is a vertex-blockage by Lemma 3.2. This easily implies that $2 \beta \leq \beta^{\prime}$.

Suppose now that $U$ is a minimum vertex-blockage in $G$. If $u \in U$ is a vertex of degree $d$, split $u$ into $d$ new vertices $u_{1}, \ldots, u_{d}$, with $u_{i}$ joined only to the $i$ th neighbor of $u(i=1, \ldots, d)$. This operation can be performed on the surface for all vertices in $U$ simultaneously. Since $U$ is a blockage, the
resulting graph contains no onesided cycles. We now start identifying some of the new vertices corresponding to $\Pi$-consecutive neighbors of $u$, say $u_{i}$ and $u_{i+1}$. We perform such identifications on the surface as long as possible so that the resulting graph $G^{\prime}$ contains no onesided cycles.

Let $B \subseteq E(M)$ be the set of those edges of $M$ that correspond to those $\Pi$-consecutive pairs $u_{i}, u_{i+1}$ that have not been identified. Since $G^{\prime}$ contains no onesided cycles, $B$ is an edge-blockage. Moreover, since every further identification gives rise to a onesided cycle, $B$ is a minimal edge-blockage (with respect to inclusion). It is also obvious that $V\left(\Gamma\left(B^{*}\right)\right) \cap V(G) \subseteq U$. By Lemma 3.2 we thus have:

$$
\begin{aligned}
|B| & \leq 2\left|V\left(\Gamma\left(B^{*}\right)\right) \cap V(G)\right|+2 g-2 \\
& \leq 2|U|+2 g-2=2 \beta+2 g-2 .
\end{aligned}
$$

This implies the second inequality in (10).
Relation (11) follows by duality, while (12) is proved analogously.
Corollary 3.4. Let $G$ be a graph that is $\Pi$-embedded in $\mathbb{N}_{g}$. Then

$$
\begin{aligned}
\mathbf{g}(G) & \leq \frac{1}{4} \beta^{\prime}(G, \Pi)+\frac{g}{4} \\
\mathbf{g}(G) & \leq \frac{1}{2} \beta(G, \Pi)+\frac{3 g-2}{4}, \text { and } \\
\mathbf{g}(G) & \leq \frac{1}{2} \beta^{*}(G, \Pi)+\frac{3 g-2}{4}
\end{aligned}
$$

Proof. Let $B$ be a minimum edge-blockage. By Lemma 3.1(b), $\Gamma\left(B^{*}\right)$ defines a crossing-free blockage $\Gamma=\left\{\gamma_{1}, \ldots, \gamma_{p}\right\}$. Clearly, $\sum_{i} \operatorname{cr}\left(\gamma_{i}, G\right)=$ $\frac{1}{2}\left|B^{*}\right|=\frac{1}{2}|B|=\frac{1}{2} \beta^{\prime}(G, \Pi)$. By Lemma 3.1(c), it follows that $\Gamma$ contains at most $\frac{g}{2}$ twosided curves. Consequently, ord $\left.(\Gamma, G) \leq \frac{1}{2} \sum_{i} \operatorname{cr}\left(\gamma_{i}, G\right)+\frac{1}{2} \right\rvert\,\{i \mid$ $\gamma_{i}$ is twosided $\} \left\lvert\, \leq \frac{1}{4} \beta^{\prime}(G, \Pi)+\frac{g}{4}\right.$. By Lemma 2.1, $\mathbf{g}(G) \leq \operatorname{ord}(\Gamma, G)$. This proves the first inequality. The second and the third inequality follow from the first one by (10) and (11), respectively.

## 4 Unstable faces and blockages

Let $\Pi_{0}$ be an embedding of a graph $G$. Suppose that there is a facial walk $F$ in which some vertex $v$ appears twice. Then there is a simple closed curve $\gamma$ in the surface which is contained in the face bounded by $F$ such that $\gamma \cap G=\{v\}$ and $\gamma$ intersects $F$ in two distinct appearances of $v$ in $F$. If $\gamma$ is contractible and its interior contains a vertex or an edge of $G$, then
we delete the vertices and edges of $G$ in the interior of $\gamma$. This operation is called an elementary reduction of type $I$.

Suppose now that there are facial walks $F$ and $F^{\prime}$ such that there exist distinct vertices $v, v^{\prime} \in V(F) \cap V\left(F^{\prime}\right)$. Then there is a simple closed curve $\gamma$ in the surface which is composed of two segments $\alpha, \beta$ joining $v$ and $v^{\prime}$ in the faces bounded by $F$ and $F^{\prime}$, respectively. If $\gamma$ is contractible and its interior contains at least two edges of $G$, then we replace all edges and vertices in its interior by a single edge joining $v$ and $v^{\prime}$. Such an operation is called an elementary reduction of type $I I$.

The embedded graph $G$ is essentially 3-connected if no elementary reductions of type I or II are possible. See also [5]. An obvious property of elementary reductions is the following:

Lemma 4.1. Let $\Pi$ be an embedding of a graph $G$. If the $\Pi^{\prime}$-embedded graph $G^{\prime}$ is obtained from $G$ by a sequence of elementary reductions, then $\mathbf{g}\left(G^{\prime}\right)=$ $\mathbf{g}(G)$ and $\beta(G, \Pi)=\beta\left(G^{\prime}, \Pi^{\prime}\right), \beta^{\prime}(G, \Pi)=\beta^{\prime}\left(G^{\prime}, \Pi^{\prime}\right)$, and $\beta^{*}(G, \Pi)=$ $\beta^{*}\left(G^{\prime}, \Pi^{\prime}\right)$.

By Lemma 4.1, we shall be able to restrict ourselves to essentially 3connected embeddings.

Suppose now that we have two embeddings, $\Pi$ and $\Pi^{\prime}$, of a graph $G$. Let $F=v_{0} e_{1} v_{1} \ldots v_{k-1} e_{k} v_{0}$ be a $\Pi$-facial walk. A subsequence $e_{i} v_{i} e_{i+1}$ (indices modulo $k$ ), $i \in\{1, \ldots, k\}$, is called an angle of $F$. The angle $e_{i} v_{i} e_{i+1}$ is identified with the angle $e_{i+1} v_{i} e_{i}$ obtained by traversing the facial walk $F$ in the reverse direction. The angle $e_{i} v_{i} e_{i+1}$ is $\left(\Pi, \Pi^{\prime}\right)$-unstable if it is not an angle of the embedding $\Pi^{\prime}$. If two consecutive angles $e_{i} v_{i} e_{i+1}$ and $e_{i+1} v_{i+1} e_{i+2}$ of the facial walk $F$ are $\left(\Pi, \Pi^{\prime}\right)$-stable but $e_{i} v_{i} e_{i+1} v_{i+1} e_{i+2}$ is not a subwalk of a $\Pi^{\prime}$-facial walk, then the angles $e_{i} v_{i} e_{i+1}$ and $e_{i+1} v_{i+1} e_{i+2}$ are said to be weakly $\left(\Pi, \Pi^{\prime}\right)$-unstable .

Suppose that $W=\ldots e_{1} v e_{2} \ldots$ and $W^{\prime}=\ldots e_{3} v e_{4} \ldots$ are walks in a $\Pi^{\prime}-$ embedded graph $G$. If the edges $e_{1}, \ldots, e_{4}$ are distinct and their $\Pi^{\prime}$-clockwise order around $v$ is $e_{1} e_{3} e_{2} e_{4}$ or $e_{1} e_{4} e_{2} e_{3}$, then we say that $W$ and $W^{\prime} \Pi^{\prime}$-cross at $v$. Similarly we define $\Pi^{\prime}$-crossing of two walks at a common edge $e$.

Lemma 4.2. Let $\Pi$ and $\Pi^{\prime}$ be embeddings of a graph $G$.
(a) If evf is a $\left(\Pi, \Pi^{\prime}\right)$-unstable angle of $a \Pi$-facial walk $F$, then there is a $\Pi$-facial walk $F^{\prime}$ with an angle $e^{\prime} v f^{\prime}$ such that $F$ and $F^{\prime} \Pi^{\prime}$-cross each other at $v$.
(b) Suppose that dve and euf are weakly $\left(\Pi, \Pi^{\prime}\right)$-unstable angles of a $\Pi$ facial walk $F$. Let $F^{\prime}=\ldots d^{\prime} v e u f^{\prime} \ldots$ be the second $\Pi$-facial walk
containing the edge e. Then $F$ and $F^{\prime} \Pi^{\prime}$-cross each other at $e$. Moreover, either one of the angles $d^{\prime}$ ve or euf $f^{\prime}$ is $\left(\Pi, \Pi^{\prime}\right)$-unstable, or these two angles of $F^{\prime}$ are weakly $\left(\Pi, \Pi^{\prime}\right)$-unstable.

Proof. To prove (a), consider the local $\Pi^{\prime}$-clockwise ordering $e, e_{1}, \ldots, e_{s}, f$, $f_{1}, \ldots, f_{t}$ of edges around $v$. Since $e$ and $f$ are not $\Pi^{\prime}$-consecutive, we have $s \geq 1$ and $t \geq 1$. It is easy to see that there are $\Pi$-consecutive edges $e^{\prime}, f^{\prime}$ such that $e^{\prime}=e_{i}$ for some $i(1 \leq i \leq s)$, and $f^{\prime}=f_{j}$ for some $j(1 \leq j \leq t)$, or vice versa. This implies (a).

Claim (b) is obvious and we leave the details for the reader.
A collection of cycles $C_{1}, \ldots, C_{k}$ is called a collection of bouquets if there exist vertices $x_{1}, \ldots, x_{p}$ such that every cycle $C_{i}(1 \leq i \leq k)$ contains precisely one of these vertices and such that for any two distinct cycles $C_{i}, C_{j}$ ( $1 \leq i<j \leq k$ ), the intersection $C_{i} \cap C_{j}$ is either empty, one of the vertices $x_{1}, \ldots, x_{p}$, or an edge incident to one of these vertices.

Part (a) of the following lemma is proved in [4], while part (b) is easy to see (cf., e.g., [6]).

Lemma 4.3. Let $G$ be a graph embedded in a surface of Euler genus $g$, and let $C_{1}, \ldots, C_{k}$ be a collection of bouquets of cycles of $G$.
(a) If $C_{1}, \ldots, C_{k}$ are noncontractible and pairwise nonhomotopic then $k \leq$ $3 g$.
(b) If no subset of $C_{1}, \ldots, C_{k}$ separates the surface then $k \leq g$.

The proof of the next lemma is essentially contained in [6].
Lemma 4.4. Let $G$ be a $\Pi^{\prime}$-embedded graph and let $\left\{\left(C_{i}, C_{i}^{\prime}\right) \mid i=1, \ldots, k\right\}$ be a collection of pairs of closed walks of $G$ with the following properties:
(a) $C_{1}, \ldots, C_{k}$ are distinct cycles of $G$ and no two of them are $\Pi^{\prime}$ crossing.
(b) If $1 \leq i<j \leq k$ then $C_{i}$ does not $\Pi^{\prime}$-cross with $C_{j}^{\prime}$.
(c) For $i=1, \ldots, k, C_{i} \cap C_{i}^{\prime}$ is either a vertex or an edge.
(d) For $i=1, \ldots, k, C_{i}$ and $C_{i}^{\prime}$ are $\Pi^{\prime}$-crossing at their intersection.

Then the genus $\mathbf{g}\left(G, \Pi^{\prime}\right)$ of $\Pi^{\prime}$ is at least $k$.
Lemma 4.5. Let $B_{U} \subseteq E(M)$ be the set of the edges of the medial graph $M(G, \Pi)$ which correspond to the $\left(\Pi, \Pi^{\prime}\right)$-unstable and to the weakly $\left(\Pi, \Pi^{\prime}\right)$ unstable angles. If $\Pi^{\prime}$ is an orientable embedding, then $B_{U}$ is an edgeblockage for $\Pi$.

Proof. Let $C$ be a onesided cycle in $M$. An open (normal) neighborhood of $C$ is homeomorphic to the Möbius band. If $E(C) \cap B_{U}=\emptyset$, then it is easy to see that the same neighborhood would be a neighborhood of $C$ in the embedding $\Pi^{\prime}$. Since $\Pi^{\prime}$ is orientable, we conclude that $E(C) \cap B_{U} \neq \emptyset$.

Suppose that the set $\{1,2, \ldots, 2 p\}$ is partitioned into pairs $A_{i}=\left\{a_{i}, b_{i}\right\}$, where $a_{i}<b_{i}, i=1, \ldots, p$. Suppose that $1 \leq i \leq p$ and $1 \leq j \leq p$ and that $b_{i} \geq a_{j}$ and $b_{j} \geq a_{i}$. Then the pair $A_{i}, A_{j}$ is called a canonical pair. An integer $l \in\{1,2, \ldots, 2 p\}$ is covered by this canonical pair if either
(a) $i=j$ and $a_{i} \leq l \leq b_{i}$, or
(b) $i \neq j$ and $l$ is either between $a_{i}$ and $a_{j}$ or between $b_{i}$ and $b_{j}$.

Lemma 4.6. Under the assumptions given above, there is a set of at least $\lceil\sqrt{p / 20}\rceil$ canonical pairs such that every $l \in\{1,2, \ldots, 2 p\}$ is covered by at most one of these pairs.

Proof. The proof is by induction on $p$. The proof is obvious for $p \leq 20$ and easy for $21 \leq p \leq 80$ (where we need only two canonical pairs).

Suppose now that $p \geq 81$. Let $q=\lfloor p / 2\rfloor$. Let us first consider the case when at least $\lceil p / 3\rceil$ pairs $A_{i}$ satisfy $a_{i} \leq 2 q$ and $b_{i}>2 q$. Let $Z$ be the set of all such pairs. Define a partial order $\preceq$ on $Z$ by $A_{i} \preceq A_{j}$ if $a_{i} \leq a_{j}$ and $b_{i} \leq b_{j}$. By the Dilworth Theorem, this partial order either contains a chain or an antichain of cardinality $z=\lceil\sqrt{|Z|}\rceil \geq\lceil\sqrt{p / 3}\rceil$. If $A_{i_{1}}, \ldots, A_{i_{z}}$ is a chain or an antichain, where $a_{i_{1}}<a_{i_{2}}<\cdots<a_{i_{z}}$, then consecutive pairs in this order are canonical pairs that cover pairwise disjoint subsets of $\{1, \ldots, 2 p\}$. This gives rise to at least $\lfloor z / 2\rfloor$ canonical pairs. Since $p \geq 81$, $\lfloor z / 2\rfloor \geq \frac{1}{2} \sqrt{p / 3}-\frac{1}{2} \geq \sqrt{p / 20}$. This completes the proof in this case.

Suppose now that there are less than $\lceil p / 3\rceil$ such pairs. The remaining subset of at least $\lceil 2 p / 3\rceil$ pairs $A_{i}$ gives rise to two subsets containing $p_{1}$ and $p_{2}$ pairs, respectively, such that the pairs in the first set are contained in $\{1, \ldots, 2 q\}$, and the pairs from the second set are contained in $\{2 q+$ $1, \ldots, 2 p\}$. Note that $p_{1}+p_{2} \geq\lceil 2 p / 3\rceil$ and that $p_{1} \leq\lfloor p / 2\rfloor$ and $p_{2} \leq\lceil p / 2\rceil$. In fact, we may assume that $p_{1}, p_{2} \leq p / 2$. (If $p_{2}>p / 2$, then we take $q=\lceil p / 2\rceil$ and repeat the above proof.)

By the induction hypothesis, these sets of pairs contain at least $\rho=$ $\left\lceil\sqrt{p_{1} / 20}\right\rceil+\left\lceil\sqrt{p_{2} / 20}\right\rceil$ canonical pairs that cover disjoint sets. The above conditions on $p_{1}, p_{2}$ imply that $\rho \geq \sqrt{(p / 2) / 20}+\sqrt{(p / 6) / 20}>\sqrt{p / 20}$. This completes the proof.

Theorem 4.7. Let $G$ be a graph that is $\Pi$-embedded in the nonorientable surface $\mathbb{N}_{g}$. Then

$$
\begin{equation*}
\frac{1}{2} \beta^{*}(G, \Pi)-(64 g)^{2} \leq \mathbf{g}(G) \leq \frac{1}{2} \beta^{*}(G, \Pi)+\frac{3 g-2}{4} \tag{13}
\end{equation*}
$$

Proof. The second inequality in (13) holds by Corollary 3.4. To prove the first one, it suffices to verify that the bound $\mathbf{g}(G) \geq \frac{1}{2}|\mathcal{F}|-(64 g)^{2}$ holds for some face-blockage $\mathcal{F}$ (not necessarily a minimum one). By Lemma 4.1, we may assume that the $\Pi$-embedded graph $G$ is essentially 3 -connected.

Let $\Pi^{\prime}$ be an orientable embedding of $G$ with genus $\mathbf{g}(G)$. Let $B_{U} \subseteq$ $E(M)$ be the set of those edges of the medial graph $M(G, \Pi)$ which correspond to the $\left(\Pi, \Pi^{\prime}\right)$-unstable and to the weakly $\left(\Pi, \Pi^{\prime}\right)$-unstable angles. By Lemma 4.5, the set $B_{U}$ is an edge-blockage.

If a vertex $v$ appears more than once on a facial walk $F$, then we say that the angles of $F$ at the appearances of $v$ are 1-singular. If there are distinct facial walks $F, F^{\prime}$ such that there exist distinct vertices $v, v^{\prime} \in V(F) \cap V\left(F^{\prime}\right)$ which are not consecutive on (at least) one of these facial walks, then we say that the angles of $F$ and of $F^{\prime}$ at $v$ and $v^{\prime}$ are 2 -singular. For $i=1,2$, let $B_{i} \subseteq E(M)$ be the set of the edges which correspond to the $i$-singular angles. Since $G$ is essentially 3 -connected, the edges in $B_{i}^{*}$ correspond to the edges in noncontractible cycles of length $2 i$ in the vertex-face graph $\Gamma$.

Let $B$ be an edge-blockage contained in $B_{U} \cup B_{1} \cup B_{2}$ of minimum cardinality. Let $\Lambda=\Gamma\left(B^{*}\right)$ be the subgraph of $\Gamma$ generated by the edges dual to $B$.

Consider the connected components of $\Lambda$ which are cycles. On each of these cycles, select a vertex, and let $A_{0}$ be the set of all selected vertices. By Lemma 3.1(c), no subset of these cycles separates the surface and hence, by Lemma $4.3(\mathrm{~b}),\left|A_{0}\right| \leq g$.

Denote by $A_{3}$ the set of vertices of $\Lambda$ containing $A_{0}$ and all vertices of degree $>2$ in $\Lambda$. Let $A_{4}$ be the set of all vertices of $\Lambda$ whose distance in $\Lambda$ from $A_{3}$ is 1 or 2 . By (5) we have

$$
\left|A_{3} \cup A_{4}\right| \leq 5\left|A_{0}\right|+\sum_{i \geq 1}(1+2 \cdot(2 i+2)) n_{i} \leq 5 g+9 \sum_{i \geq 1} i n_{i} \leq 14 g-9
$$

Similar arguments as used above imply that the graph $\Lambda-\left(A_{3} \cup A_{4}\right)$ is the union of $r \leq 3 g-2$ disjoint paths $P_{1}, \ldots, P_{r}$. Choose arbitrarily an orientation of each of the paths $P_{1}, \ldots, P_{r}$. If $C$ is a $\Pi$-facial walk corresponding to a vertex of $P_{i}(1 \leq i \leq r)$, let $v_{C} \in V(G)$ be the vertex of $G$ that follows $C$ in $\Lambda$ in the chosen direction of $P_{i}$. If the edge of $\Lambda$ joining $C$
and $v_{C}$ belongs to $B_{U}^{*}$, then Lemma 4.2 implies that there is a $\Pi$-facial walk $C^{\prime}$ such that $C$ and $C^{\prime} \Pi^{\prime}$-cross at $v_{C}$ or $\Pi^{\prime}$-cross at a common edge incident with $v_{C}$. We say that $C^{\prime}$ is a mate of $C$. If the edge joining $C$ and $v_{C}$ is in $B_{2}^{*}$, then we let the mate $C^{\prime}$ of $C$ be a face such that $C$ and $C^{\prime}$ intersect at $v_{C}$ and at another vertex that is not adjacent with $v_{C}$.

Let $A_{1}$ be the set of vertices of $\Lambda$ which correspond to $\Pi$-facial walks that are not cycles of $G$. For $x \in A_{1}$, let $F$ be the corresponding facial walk, and let $v \in V(F)$ be a vertex of $G$ that appears twice in $F$. Since $G$ is essentially 3 -connected, $v$ and $F$ determine a noncontractible cycle of length 2 in $\Gamma$. (Possibly, the edges of that cycle are not contained in $\Lambda$.) Choose one such 2-cycle for every $x \in A_{1}$, and let $C_{1}, \ldots, C_{k}\left(k=\left|A_{1}\right|\right)$ be the resulting collection of cycles of $\Gamma$. Clearly, $C_{1}, \ldots, C_{k}$ form a bouquet collection in $\Gamma$. If $k>9 g$, then Lemma 4.3(a) implies that four of the cycles are homotopic to each other, say $Q_{1}, Q_{2}, Q_{3}, Q_{4}$. These cycles of length 2 in $\Gamma$ may intersect but their vertices corresponding to faces of $G$ are distinct. We may assume that $C_{1}$ and $C_{4}$ bound a cylinder (or a disk) that contains $C_{2}$ and $C_{3}$. Now, we add to $B^{*}$ the edges of $Q_{1}$ and $Q_{4}$. This gives rise to a new edge-blockage contained in $B_{U} \cup B_{1} \cup B_{2}$ whose cardinality is $\leq|B|+4$. Since $Q_{2}$ and $Q_{3}$ are contained in the cylinder (disk) bounded by $Q_{1}$ and $Q_{4}$, we may remove the edges of $B^{*}$ incident with the vertices of $A_{1}$ that are on $Q_{2}$ and $Q_{3}$ and also remove the edges of $Q_{4}$ and still have a blockage $B^{\prime} \subset B^{*} \cup E\left(C_{1}\right)$. Clearly, $\left|B^{\prime}\right|<\left|B^{*}\right|$, a contradiction. Consequently, $\left|A_{1}\right| \leq 9 g$.

Let $A_{2}$ be the set of vertices of $P_{1}, \ldots, P_{r}$ that are not in $A_{1}$ and correspond to $\Pi$-facial cycles which intersect their mate in more than just a vertex or an edge. Let $C$ be such facial cycle, and let $C^{\prime}$ be its mate. Since $G$ is essentially 3 -connected, there is a noncontractible 4 -cycle $Q$ in $\Gamma$ whose vertices are $C, C^{\prime}, v_{C}$ and another vertex $y \in V\left(C \cap C^{\prime}\right)$. Let $Z$ be the set of all such 4-cycles of $\Gamma$. For $Q \in Z$, we denote its vertices by $C(Q), C^{\prime}(Q)$, $v_{C}(Q)$, and $y(Q)$.

It is a simple exercise to prove that there is a subset $Z_{1} \subseteq Z$ of cardinality $\geq \frac{1}{9}\left|A_{2}\right|$ such that for any $Q_{1}, Q_{2} \in Z_{1}, v_{C}\left(Q_{1}\right) \neq y\left(Q_{2}\right)$ and $C\left(Q_{1}\right) \neq$ $C^{\prime}\left(Q_{2}\right)$. (Hint: Consider the directed graph on all $v_{C}$ and $y$-vertices, with an edge from $v_{C}(Q)$ to $y(Q)$ for each $Q \in Z$, and observe that the outdegree of this digraph is at most 1.) Clearly, $V\left(Q_{1}\right) \cap V\left(Q_{2}\right) \subseteq\left\{C^{\prime}\left(Q_{1}\right), y\left(Q_{1}\right)\right\}$. If $Q_{1}$ and $Q_{2}$ intersect in two vertices, then we may assume that their intersection is the edge $C^{\prime}\left(Q_{1}\right) y\left(Q_{1}\right)=C^{\prime}\left(Q_{2}\right) y\left(Q_{2}\right)$.

Let $z=\sqrt{\left|Z_{1}\right|}$. If there is a vertex $y$ such that $y=y(Q)$ for at least $z$ members of $Z_{1}$, then those 4-cycles in $Z_{1}$ that contain $y$ form a collection of bouquets of cardinality at least $z$. Otherwise, there is a subset of $Z_{1}$ of
cardinality $\geq z$ such that no two cycles in this subset have their $y$-vertex in common. Again, this subset forms a collection of bouquets. If $z>9 g$, then four of the cycles in that collection of bouquets are homotopic, and a proof similar to the above proof of the fact that $\left|A_{1}\right| \leq 9 g$ yields a contradiction to the minimality of $B$. This shows that $z \leq 9 g$ and, therefore, $\left|A_{2}\right| \leq 729 g^{2}$.

Let $F_{1}, \ldots, F_{N}$ be the facial cycles corresponding to the vertices on $P_{1}, \ldots, P_{r}$ which are not in $A_{1} \cup A_{2}$, enumerated in the order of the paths $P_{1}, \ldots, P_{r}$ and with respect to their selected orientation. Let $F_{1}^{\prime}, \ldots, F_{N}^{\prime}$ be their mates. Since the facial cycles corresponding to the vertices in $\Lambda$ form a face-blockage, we have

$$
\begin{align*}
N & \geq \beta^{*}(G, \Pi)-\left|A_{1} \cup A_{2}\right|-\left|A_{3} \cup A_{4}\right| \\
& \geq \beta^{*}(G, \Pi)-(27 g+1)^{2} . \tag{14}
\end{align*}
$$

If $i, j \in\{1, \ldots, N\}$ and $j-i \geq 2$, then we say that $\{i, j\}$ is a bad pair if either $F_{i}$ and $F_{j}$, or $F_{i}$ and $F_{j}^{\prime}$ intersect and $\Pi^{\prime}$-cross each other. Let $M$ be a set of bad pairs of maximum cardinality such that no two members of $M$ have an element in common. Our goal is to prove that $|M|=O\left(g^{2}\right)$.

Each bad pair $\{i, j\}$ determines a path $Q_{i j}$ joining two vertices of $\Lambda$ : If $F_{i}$ and $F_{j} \Pi^{\prime}$-cross at vertex $x$, then $Q_{i j}$ is the path of length 2 connecting $F_{i}$ and $F_{j}$ through $x$. If $F_{i}$ and $F_{j}^{\prime} \Pi^{\prime}$-cross at vertex $x$, then $Q_{i j}$ is the path of length 3 connecting $F_{i}$ and a vertex in $F_{j} \cap F_{j}^{\prime}$ through $x$. Clearly, $E\left(Q_{i j}\right) \subseteq B_{U}^{*}$.

If $\{i, j\}$ is a bad pair and $F_{i}$ and $F_{j}$ are in the same path $P_{a}(1 \leq a \leq r)$, then $Q_{i j}$ and the edges of $P_{a}$ determine a cycle $R_{i j}$ which is called the canonical cycle of the bad pair $\{i, j\}$. Observe that

$$
\begin{equation*}
\left|E\left(Q_{i j}\right)\right|<\frac{1}{2}\left|E\left(R_{i j}\right)\right| . \tag{15}
\end{equation*}
$$

Suppose that $\{i, j\}$ and $\left\{i^{\prime}, j^{\prime}\right\}\left(i<j, i^{\prime}<j^{\prime}\right)$ are disjoint bad pairs such that $i^{\prime}<j$ and $i<j^{\prime}$. If $F_{j}$ and $F_{j^{\prime}}$ are in the same path $P_{a}(1 \leq a \leq r)$ and $F_{i}$ and $F_{i^{\prime}}$ are in the same path $P_{b}(1 \leq b \leq a)$, then there is a cycle $R_{i j, i^{\prime} j^{\prime}}$ in $\Lambda$ that is composed of $Q_{i j}, Q_{i^{\prime} j^{\prime}}$ and two paths $P_{j j^{\prime}} \subseteq P_{a}$ and $P_{i i^{\prime}} \subseteq P_{b}$ joining the "upper" and "lower" ends of $Q_{i j}$ and $Q_{i^{\prime} j^{\prime}}$, respectively. The cycle $R_{i j, i^{\prime} j^{\prime}}$ is called the canonical cycle of bad pairs $\{i, j\}$ and $\left\{i^{\prime}, j^{\prime}\right\}$. We shall need an analogy of (15). That is not automatic, but if $\left|j-j^{\prime}\right| \geq 4$, then the length of the segment $P_{j j^{\prime}}$ is at least 7. Consequently,

$$
\begin{equation*}
\left|E\left(Q_{i j}\right)\right|+\left|E\left(Q_{i^{\prime} j^{\prime}}\right)\right|<\left|E\left(P_{j j^{\prime}}\right)\right| . \tag{16}
\end{equation*}
$$

We can view $P_{1} \cup \cdots \cup P_{r}$ as being a single path by adding auxiliary edges joining the end of $P_{l}$ with the beginning of $P_{l+1}, l=1, \ldots, r-1$. Then we can define canonical cycles for bad pairs (or pairs of bad pairs) also when the ends of $Q_{i j}$ (and $Q_{i^{\prime} j^{\prime}}$ ) are not in the same path(s) $P_{a}$ (and $P_{b}$ ). The canonical cycles that use the auxiliary edges are called fake canonical cycles; the others are said to be genuine.

In order to meet the condition $\left|j-j^{\prime}\right| \geq 4$ needed for (16), we order the bad pairs in $M$ according to their larger members $j$, and let $M_{1}$ be the subset consisting of every fourth bad pair in this order.

Lemma 4.6 shows that there is a set of at least $\left\lceil\sqrt{\left|M_{1}\right| / 20}\right\rceil$ canonical cycles (using only bad pairs in $M_{1}$ ) whose intersections with $P_{1} \cup \cdots \cup P_{r}$ are pairwise disjoint. Since $r \leq 3 g-2$, at most $3 g-3$ of these canonical cycles are fake. Let $R_{1}, \ldots, R_{s}\left(s \geq\left\lceil\sqrt{\left|M_{1}\right| / 20}\right\rceil-3 g+3\right)$ be the subset of genuine canonical cycles. These canonical cycles are disjoint except that they may have a vertex in common if the mate $F_{j}^{\prime}$ of $F_{j}$ is the same as the mate $F_{l}^{\prime}$ of $F_{l}$, and $F_{j}, F_{l}$ are in distinct canonical cycles. Therefore, $R_{1}, \ldots, R_{s}$ form a collection of bouquets.

If one of these cycles, say $R_{l}=R_{i j}$ (or $R_{l}=R_{i j, i^{\prime} j^{\prime}}$ ) would be contractible, then the replacement in $B^{*}$ of $E\left(R_{l}\right) \cap P_{a}$ (or $E\left(P_{j j^{\prime}}\right)$ ) with $Q_{i j}$ (or $Q_{i j} \cup Q_{i^{\prime} j^{\prime}}$ ) would give rise to another blockage. By (15) (or (16)), this blockage would contradict minimality of $B$. Therefore, $R_{l}$ is noncontractible. Similar conclusion holds if two of these genuine canonical cycles are homotopic (in which case we can add to $B^{*}$ the missing edges of one of them and remove the edges of the second one). Lemma 4.3 implies that $s \leq 3 g$. Consequently, $|M| \leq 4\left|M_{1}\right| \leq 3240 g^{2}$.

Let $A$ be the set of facial cycles $F_{l}$ such that $l$ is contained in some bad pair in $M$. As proved above, $|A| \leq 2 \cdot 3240 g^{2}$. Let $C_{1}, \ldots, C_{t}$ be a maximum subsequence of $F_{1}, \ldots, F_{N}$ such that none of $C_{i}$ is in $A$ and such that, for $i=1, \ldots, t-1$, if $C_{i}=F_{j}$, then $C_{i+1} \neq F_{j+1}$. Clearly,

$$
\begin{equation*}
t \geq \frac{1}{2}(N-|A|) \geq \frac{1}{2} N-3240 g^{2} \tag{17}
\end{equation*}
$$

For $j=1, \ldots, t$, let $C_{j}^{\prime}$ be the mate of $C_{j}$. Let us consider the collection of pairs

$$
\mathcal{C}=\left\{\left(C_{j}, C_{j}^{\prime}\right) \mid j=1, \ldots, t\right\}
$$

We claim that $\mathcal{C}$ satisfies conditions (a)-(d) of Lemma 4.4. No facial walk $C_{i}$ is in $A_{1} \cup A_{2}$. Therefore, every $C_{i}$ is a cycle and (c) holds. Since the cycles in $A$ do not participate in the sequence $C_{1}, \ldots, C_{t}$, the pairs in $\mathcal{C}$ satisfy (a) and (b). Clearly, (d) is also satisfied.

By Lemma 4.4 and inequalities (14) and (17),

$$
\mathbf{g}(G)=\mathbf{g}\left(G, \Pi^{\prime}\right) \geq|\mathcal{C}| \geq \frac{1}{2} N-3240 g^{2} \geq \frac{1}{2} \beta^{*}(G, \Pi)-(64 g)^{2}
$$

The proof is complete.
The "error" term $(64 g)^{2}$ in (13) is not best possible. There are examples which show that such term of order $\Omega(g)$ is necessary, and we conjecture that (13) can be improved to

$$
\mathbf{g}(G) \geq \frac{1}{2} \beta^{*}(G, \Pi)-O(g)
$$

Lemma 2.1, Theorem 4.7, and Corollary 3.3 imply:
Corollary 4.8. Let $G$ be a graph embedded in $\mathbb{N}_{g}$, and let $r$ be the minimum order of a crossing-free blockage. Then

$$
r-(64 g)^{2} \leq \mathbf{g}(G) \leq r
$$

Finally, let us observe that Corollary 3.3 implies that $\beta(G, \Pi)$ and $\beta^{*}(G, \Pi)$ cannot differ too much. Therefore, $\mathbf{g}(G)$ is also approximately equal to $\beta(G, \Pi)$, up to a term which depends on $g$ only.

It is not clear if there is an efficient algorithm for finding a minimum (crossing-free) blockage or its approximation for a graph embedded in $\mathbb{N}_{g}$. For every fixed $g$, this task is solvable in polynomial time since there is only a bounded number of possibilities for homotopies of curves in an optimum crossing-free blockage. However, this approach seems complicated, and we restrain of describing further details. The case when $g=2$ is described in [9].
